## CHAPTER 10 -- GRAVITATION

10.1) According to Newton, the magnitude of the gravitational force between any two bodies will always be equal to $G m_{1} m_{2} / r^{2}$.
a.) The gravitation force you exert on your friend will be:

$$
\begin{aligned}
\mathrm{F}_{\text {on friend }} & =\mathrm{G} \quad \mathrm{~m}_{\text {you }} \mathrm{m}_{\mathrm{fr}} / \mathrm{r}^{2} \\
& =\left(6.67 \times 10^{-11} \mathrm{nt} \cdot \mathrm{~m}^{2} / \mathrm{kg}^{2}\right)(80 \mathrm{~kg})(60 \mathrm{~kg}) /(5 \mathrm{~m})^{2} \\
& =1.28 \times 10^{-8} \mathrm{nts} .
\end{aligned}
$$

Note: If you cut a ping pong ball into a million and a half or so pieces, this force would approximately equal the weight of one piece.
b.) As for the acceleration, Newton's Second Law yields:

$$
\begin{aligned}
& \underline{\underline{F_{x}}}: \\
& \mathrm{F}_{\mathrm{fr}}=\mathrm{m}_{\mathrm{fr}} \mathrm{a} \\
& \Rightarrow \mathrm{a}=\mathrm{F}_{\mathrm{fr}} \quad / \mathrm{m}_{\mathrm{fr}} \\
& =\left(1.28 \times 10^{-8} \mathrm{nt}\right) /(60 \mathrm{~kg}) \\
& \Rightarrow \quad=2.13 \times 10^{-10} \mathrm{~m} / \mathrm{s}^{2} \text {. }
\end{aligned}
$$

Note: You can now see why you don't feel a gravitational force when you brush past a friend on the street. The Universal Gravitational Constant $G$ is so small that at least one of the masses has to be enormous before gravitational effects become noticeable.
10.2) Figure I below shows an f.b.d. for the forces acting on the top mass, complete with components. Figure II below shows how the radius $r$ of the orbits can be determined.

Due to symmetry, the horizontal components will add to zero leaving only the vertical components with which to contend. Noting that the masses are all the same and the radius of the circular motion is $.577 d$, we can use N.S.L. in the centerseeking direction to write:

$$
\begin{aligned}
& \frac{\sum \mathrm{F}_{\text {center-seeking }}:}{-\mathrm{F}_{\mathrm{g}} \cos \theta}-\mathrm{F}_{\mathrm{g}} \cos \theta=-\mathrm{ma}_{\mathrm{c}} \\
& \Rightarrow \quad 2\left[\mathrm{Gm}^{2} / \mathrm{d}^{2}\right] \cos 30^{\circ}=\mathrm{m}\left(\mathrm{v}^{2} / \mathrm{r}\right) \\
& \\
& \\
& \\
& \\
& \quad \Rightarrow \quad \mathrm{v}=(\mathrm{Gm} / \mathrm{d})^{1 / 2} .
\end{aligned}
$$

10.3) This is a straight freefall problem (i.e., although we will be using Newton's gravitational force, the force is not acting centripetally).
a.) The earth to moon distance (center of mass to center of mass) is $3.82 \times 10^{8}$ meters plus $1.74 \times 10^{6}$ meters plus $6.37 \times 10^{6}$ meters, or approximately $3.9 \times 10^{8}$ meters. Summing the forces in the direction of freefall, we can write:

$$
\begin{aligned}
& \underline{\sum \mathrm{F}_{\mathrm{r}}:} \\
& \quad-\mathrm{Gm}_{\mathrm{m}} \mathrm{~m}_{\mathrm{e}} / \mathrm{r}^{2} \\
& \Rightarrow \quad-\mathrm{m}_{\mathrm{m}} \mathrm{a} \\
& \Rightarrow \quad \mathrm{a}
\end{aligned}=\mathrm{Gm}_{\mathrm{e}} / \mathrm{r}^{2} .
$$

b.) The distance between the moon's center of mass and the earth's center of mass just before they strike one another will be the sum of their radii. Using that observation and repeating the calculation done in Part $a$, we get:

$$
\begin{aligned}
& \underline{\sum F_{r}:} \\
& \quad-\mathrm{Gm}_{\mathrm{m}} \mathrm{~m}_{\mathrm{e}} / \mathrm{r}_{\mathrm{e}, \mathrm{~m}}^{2}=-\mathrm{m}_{\mathrm{m}} \mathrm{a}^{\mathrm{a}} \\
& \quad \Rightarrow \quad \mathrm{a}=\mathrm{Gm}_{\mathrm{e}} / \mathrm{r}_{\mathrm{e}, \mathrm{~m}}^{2} \\
& \quad=\left(6.67 \times 10^{-11} \mathrm{nt} \cdot \mathrm{~m}^{2} / \mathrm{kg}^{2}\right)\left(5.98 \times 10^{24} \mathrm{~kg}\right) /\left(8.11 \times 10^{6} \mathrm{~m}\right)^{2} \\
& \quad=6.06 \mathrm{~m} / \mathrm{s}^{2} .
\end{aligned}
$$

c.) The acceleration is not a constant (obviously), so kinematics is out. The best approach is using conservation of energy. Remembering that the potential energy function for a varying gravitational field is $U=-G m_{1} m_{2} / r$ (a scalar), we can write:

$$
\begin{aligned}
& \sum \mathrm{KE}_{1}+\quad \sum \mathrm{U}_{1}+\sum \mathrm{W}_{\mathrm{ext}}=\sum \mathrm{KE}_{2}+\quad \sum \mathrm{U}_{2} \\
& \text { (0) }+\left(-\mathrm{Gm}_{\mathrm{m}} \mathrm{~m}_{\mathrm{e}} / \mathrm{r}\right)+(0)=(1 / 2) \mathrm{m}_{\mathrm{m}} \mathrm{v}^{2}+\left[-\mathrm{Gm}_{\mathrm{m}} \mathrm{~m}_{\mathrm{e}} /\left(\mathrm{r}_{\mathrm{m}}+\mathrm{r}_{\mathrm{e}}\right)\right] \\
& \Rightarrow \quad \mathrm{v}=\left[2 \mathrm{Gm}_{\mathrm{e}}\left[-1 / \mathrm{r}+1 /\left(\mathrm{r}_{\mathrm{m}}+\mathrm{r}_{\mathrm{e}}\right)\right]\right]^{1 / 2} \\
& =\left[2\left(6.67 \times 10^{-11} \mathrm{nt} \cdot \mathrm{~m}^{2} / \mathrm{kg}^{2}\right)\left(5.98 \times 10^{24} \mathrm{~kg}\right)\left[-1 /\left(3.9 \times 10^{8} \mathrm{~m}\right)+1 /\left(1.74 \times 10^{6}+6.37 \times 10^{6} \mathrm{~m}\right)\right]\right]^{1 / 2} \\
& \Rightarrow \quad \mathrm{v}=9814 \mathrm{~m} / \mathrm{s} \text {. }
\end{aligned}
$$

d.) If the earth is allowed to move, we have to take into consideration its kinetic energy at the end of the freefall (its initial kinetic energy is zero). This means we now have a second unknown--the earth's velocity--to deal with. To get an expression relating the earth's velocity $v_{e}$ to the moon's velocity $v_{m}$, note that the only force acting in the system--gravity-is internal to the system (that is, the moon exerts a gravitational force on the earth and the earth exerts an equal and opposite gravitational force on the moon). That means momentum is conserved.

With everything starting from rest, the system's initial net momentum (and the system's subsequent net momentum) is zero. Using that bit of information, we can write:

$$
\begin{gathered}
\quad \mathrm{p}_{\mathrm{o}}=\mathrm{p}_{\text {just before impact }} \\
0=-\mathrm{m}_{\mathrm{m}} \mathrm{v}_{\mathrm{m}}+\mathrm{m}_{\mathrm{e}} \mathrm{v}_{\mathrm{e}} \\
\Rightarrow \quad \mathrm{v}_{\mathrm{e}} / \mathrm{v}_{\mathrm{m}}=\mathrm{m}_{\mathrm{m}} / \mathrm{m}_{\mathrm{e}} .
\end{gathered}
$$

Knowing the mass of the earth and moon, we now have the relationship we need between the earth's velocity and the moon's velocity (i.e., our second equation).

## 10.4)

a.) The magnitude of the force applied to $m_{1}$ a distance $r$ from the planet's center is:

$$
\mathrm{F}=\mathrm{G}\left(\mathrm{~m}_{\text {inside sphere }}\right) \mathrm{m}_{1} / \mathrm{r}^{2},
$$

where $\mathrm{m}_{\text {inside sphere }}$ is the mass inside the sphere upon which the body sits. To determine that mass, define a differential sphere of radius $a$ and thickness $d a$. Its differential volume will be its surface area times its thickness, or $d V=$ $\left(4 \pi a^{2}\right) d a$. Defining the volume density function to be $\rho$, we can write:

$$
\begin{aligned}
\mathrm{m}_{\text {insidesph }} & =\int \rho d v \\
& =\int_{a=0}^{r}\left[\frac{m_{p}}{r_{p}^{4}} a\right]\left[4 \pi a^{2} d a\right] \\
& =\frac{4 \pi m_{p}}{r_{p}^{4}} \int_{a=0}^{r} a^{3} d a \\
& =\frac{4 \pi m_{p}}{r_{p}^{4}}\left[\frac{a^{4}}{4}\right]_{a=0}^{r} \\
& =\frac{\pi m_{p}}{r_{p}^{4}} r^{4} .
\end{aligned}
$$

Using this, we can write:

$$
\begin{aligned}
\mathrm{F} & =\mathrm{G}\left(\mathrm{~m}_{\text {inside sphere }}\right) \mathrm{m}_{1} / \mathrm{r}^{2} \\
& =\mathrm{G}\left(\pi \mathrm{~m}_{\mathrm{p}} \mathrm{r}^{4} / \mathrm{r}_{\mathrm{p}}^{4}\right) \mathrm{m}_{1} / \mathrm{r}^{2} \\
& =\mathrm{Gm}_{\mathrm{p}} \mathrm{~m}_{1}\left(\pi / \mathrm{r}_{\mathrm{p}}^{4}\right) \mathrm{r}^{2} .
\end{aligned}
$$

Note that at $r=0$, we don't find a zero in the denominator as before.
b.) The potential-energy-equals-zero-point for a variable force function is ALWAYS placed where the force is zero. In this case, that is at the planet's center. If we assume the body is sitting at some position $y=r$ up the vertical axis (i.e., we are assuming the tunnel is in the vertical), then the force on the $\operatorname{mass} m_{1}$ when at an arbitrary point $y$ will be $-G m_{p} m_{1}\left(\pi / r_{p}^{4}\right) y^{2}$ (from Part a) Setting $U(y=0)=0$, we can write:

$$
\begin{aligned}
U(r)-U(y & =0)=-\int \mathbf{F} \bullet d \mathbf{r} \\
\Rightarrow U(r) & =-\int_{y=0}^{r}\left[-\frac{G m_{p} m_{1} \pi}{r_{p}^{4}} y^{2} \mathbf{j}\right] \cdot(d x \mathbf{i}+d y \mathbf{j}+d z \mathbf{k}) \\
& =\frac{G m_{p} m_{1} \pi}{r_{p}^{4}} \int_{y=0}^{r} y^{2} d y \\
& =\frac{G m_{p} m_{1} \pi}{r_{p}^{4}}\left[\frac{y^{3}}{3}\right]_{y=0}^{r} \\
& =\frac{G m_{p} m_{1} \pi}{3 r_{p}^{4}} r^{3} .
\end{aligned}
$$

Again, this makes sense. At $r=0$, the potential energy is zero.
10.5) We know the orbital distance from the earth's center of mass is $r=1.3 \times 10^{6} \mathrm{~m}$ $+6.3 \times 10^{6} \mathrm{~m}=7.6 \times 10^{6}$ meters, and we know that this is additionally the distance between the centers of mass of the two bodies (the two quantities are the same as the satellite's mass is minuscule in comparison to the earth's mass).
a.) One of the things that makes orbital problems tricky is that there are a number of ways one can determine a velocity. Conservation of energy has velocities in it, but so does N.S.L. coupled with centripetal acceleration. Knowing which approach to use in a given situation is something that comes only with experience. In this particular case, we want to look at the forces acting on the satellite.

$$
\begin{aligned}
& \underline{\sum F_{\mathrm{c}}:} \quad \\
& \quad-\mathrm{F}_{\mathrm{g}} \quad=-\mathrm{ma}_{\mathrm{c}} \\
& \Rightarrow \quad \mathrm{Gm}_{\mathrm{s}} \mathrm{~m}_{\mathrm{e}} / \mathrm{r}^{2}
\end{aligned}=\mathrm{m}_{\mathrm{s}}\left(\mathrm{v}^{2} / \mathrm{r}\right) .
$$

b.) If it takes time $T$ for the satellite to travel the circumference of the circle upon which it moves, then the ratio of those two quantities (i.e., distance/time) will yield the magnitude of its velocity. As $T$ is defined as the period of the motion (i.e., the time for one complete orbit), we can write:

$$
\begin{aligned}
& \mathrm{v}=\text { (circumference)/(period) } \\
& \begin{aligned}
&=2 \pi \mathrm{r} / \mathrm{T} \\
& \Rightarrow \quad \mathrm{~T}=2 \pi \mathrm{r} / \mathrm{v} \\
&=2 \pi\left(7.6 \times 10^{6} \mathrm{~m}\right) /(7244 \mathrm{~m} / \mathrm{s}) \\
&=6592 \text { seconds } \quad \text { (approx. } 1 \mathrm{hr}, 50 \mathrm{~min} .) .
\end{aligned}
\end{aligned}
$$

c.) The work we have to do in getting the satellite up to speed is equal to the body's final kinetic energy. The work we have to do in lifting the satellite into the appropriate orbit is equal to minus the work gravity does on the body as the body rises, or $\Delta \mathrm{U}_{\mathrm{g}}$ (remember, the work gravity itself does as the body rises is $-\Delta \mathrm{U})$. If we add these two work quantities together, we have the amount of energy we have to provide to the system to get the satellite into orbit.
. . . Or, we could simply use the modified conservation of energy equation. In that expression, the $\Sigma W_{\text {ext }}$ term denotes the extra energy needed from $u s$ to put the satellite in orbit. Using that expression, we can write:

$$
\begin{aligned}
\sum K E_{1}+\sum \mathrm{U}_{1}+\sum \mathrm{W}_{\mathrm{ext}} & =\sum \mathrm{KE}_{2}+\sum \mathrm{U}_{2} \\
(0)+\left(-G \mathrm{Gm}_{\mathrm{s}} \mathrm{~m}_{\mathrm{e}} / \mathrm{re}_{\mathrm{e}}\right)+\mathrm{E}_{\mathrm{you}} & =(1 / 2) \mathrm{m}_{\mathrm{s}} \mathrm{v}^{2}+\left(-\mathrm{Gm}_{\mathrm{s}} \mathrm{~m}_{\mathrm{e}} / \mathrm{r}\right),
\end{aligned}
$$

where $v$ is the orbital velocity of the satellite and $r$ is the orbital radius from the earth's center.

Solving yields:

$$
\begin{gathered}
\mathrm{E}_{\mathrm{you}}=(1 / 2) \mathrm{m}_{\mathrm{s}} \mathrm{v}^{2}+\mathrm{Gm}_{\mathrm{s}} \mathrm{~m}_{\mathrm{e}}\left[1 / \mathrm{r}_{\mathrm{e}}-1 / \mathrm{r}\right] \\
=.5(400 \mathrm{~kg})(7244 \mathrm{~m} / \mathrm{s})^{2}+ \\
\left(6.67 \times 10^{-11} \mathrm{nt} \cdot \mathrm{~m}^{2} / \mathrm{kg}^{2}\right)\left(5.98 \times 10^{24} \mathrm{~kg}\right)(400 \mathrm{~kg})\left[1 /\left(6.3 \times 10^{6} \mathrm{~m}\right)-1 /\left(7.6 \times 10^{6} \mathrm{~m}\right)\right] \\
\Rightarrow \mathrm{E}_{\mathrm{you}}=1.48 \times 10^{10} \text { joules. }
\end{gathered}
$$

Note: If we had used the orbital energy expression $E=-G m_{s} m_{e} / 2 r$ from the chapter, we would have ended up with $-1.05 \times 10^{10}$ joules (this, if you will remember, is $K E_{r}+U_{r}$ ). So why doesn't the orbital energy expression equal the work required to put the satellite into orbit?

The answer is simple. The body started out with potential energy. Sitting on the earth's surface with $-G m_{e} m_{s} / r_{e}=-2.53 \times 10^{10}$ joules of potential energy (put in the numbers--that's what you get). Add the energy needed to get it into orbit (i.e., the $1.48 \times 10^{10}$ joules) and you end up with the satellite's net final energy equaling $-1.05 \times 10^{10}$ joules.
d.) The earth's angular velocity is $2 \pi$ radians per 24 hours (give or take a bit). That calculates out to $\omega=7.27 \times 10^{-5}$ radians $/$ second. At the equator, the magnitude of the earth's translational velocity is $v=r_{\text {equ }} \omega=\left(6.3 \times 10^{6}\right.$ m) $\left(7.272 \times 10^{-5} \mathrm{rad} / \mathrm{sec}\right)=458 \mathrm{~m} / \mathrm{s}$.

A satellite launched in the direction of the earth's rotation at the equator will begin its trip with initial kinetic energy equal to (1/2)mve ${ }_{e}^{2}$, where $v_{e}$ is the velocity of the rotating earth.

In the case of our satellite, it would start out with kinetic energy equal to $(1 / 2)(400 \mathrm{~kg})(458 \mathrm{~m} / \mathrm{s})^{2}=4.2 \times 10^{7}$ joules worth of energy we wouldn't have to supply to the system to get it into its orbit.

It should now be obvious why launching pads in the U.S. (Cape Canaveral, for instance) are as close to the equator as possible.
e.) In 1800 revolutions, the energy lost to the satellite will be:

$$
\begin{aligned}
\mathrm{E}_{\text {lost }} & =(1800 \mathrm{rev})\left(2 \times 10^{5} \text { joules } / \mathrm{rev}\right) \\
& =3.6 \times 10^{8} \text { joules. }
\end{aligned}
$$

The amount of energy it starts out with as it traveled in its orbit is:

$$
\begin{aligned}
\mathrm{E}_{1} & =-\mathrm{Gm}_{\mathrm{e}} \mathrm{~m}_{\mathrm{s}} / 2 \mathrm{r}_{1} \\
& =-\left(6.6 \times 10^{-11} \mathrm{nt} \cdot \mathrm{~m}^{2} / \mathrm{kg} \mathrm{~g}^{2}\right)\left(5.98 \times 10^{24} \mathrm{~kg}\right)(400 \mathrm{~kg}) /\left[2\left(7.6 \times 10^{6} \mathrm{~m}\right)\right] \\
& =-1.049 \times 10^{10} \text { joules. }
\end{aligned}
$$

After losing $3.6 \times 10^{8}$ joules of energy, the satellite has:

$$
\begin{aligned}
\mathrm{E}_{2} & =\quad \mathrm{E}_{1}-\mathrm{E}_{\text {lost }} \\
& =\left(-1.049 \times 10^{10} \text { joules }\right)-\left(3.6 \times 10^{8} \text { joules }\right) \\
& =-1.085 \times 10^{10} \text { joules. }
\end{aligned}
$$

An orbit with that amount of energy must be such that:

$$
\begin{aligned}
\mathrm{E}_{2}= & -\mathrm{Gm}_{\mathrm{e}} \mathrm{~m}_{\mathrm{s}} / 2 \mathrm{r}_{2} \\
\Rightarrow \quad \mathrm{r}_{2} & =-\mathrm{Gm}_{\mathrm{e}} \mathrm{~m}_{\mathrm{s}} / 2 \mathrm{E}_{2} \\
& =-\left(6.67 \times 10^{-11} \mathrm{nt} \cdot \mathrm{~m}^{2} / \mathrm{kg}^{2}\right)\left(5.98 \times 10^{24} \mathrm{~kg}\right)(400 \mathrm{~kg}) /\left[2\left(-1.085 \times 10^{10} \mathrm{j}\right)\right] \\
& =7.35 \times 10^{6} \text { meters. }
\end{aligned}
$$

This is the distance from the earth's center. From the earth's surface, the height will be $7.35 \times 10^{6}$ meters minus $6.3 \times 10^{6}$ meters equals $1.05 \times 10^{6}$ meters.

Although the problem did not ask for the velocity of the satellite when in this orbit, we will need it later. Using N.S.L., we can write:

$$
\begin{aligned}
& \sum \mathrm{F}_{\mathrm{r}} \text { : } \\
& \mathrm{F}_{\mathrm{g}}=\mathrm{ma}_{\mathrm{c}} \\
& \Rightarrow \quad \mathrm{Gm}_{\mathrm{s}} \mathrm{~m}_{\mathrm{e}} / \mathrm{r}_{2}{ }^{2}=\mathrm{m}_{\mathrm{s}}\left(\mathrm{v}_{2}{ }^{2} / \mathrm{r}_{2}\right) \\
& \Rightarrow \quad \mathrm{v}_{2}=\left(\mathrm{Gm}_{\mathrm{e}} / \mathrm{r}_{2}\right)^{1 / 2} \\
& =\left[\left(6.67 \times 10^{-11} \mathrm{nt} \cdot \mathrm{~m}^{2} / \mathrm{kg}^{2}\right)\left(5.98 \times 10^{24} \mathrm{~kg}\right) /\left(7.35 \times 10^{6} \mathrm{~m}\right)\right]^{1 / 2} \\
& =7366 \mathrm{~m} / \mathrm{s} \text {. }
\end{aligned}
$$

f.) The retarding force does $2 \times 10^{5}$ joules per revolution of work on the satellite as the satellite moves along in its path. On average, the work done by the retarding force in one orbit will equal the average force times the average circumference of motion times $\cos 180^{\circ}$ (the retarding force and the direction of
motion will be opposite one another, hence the $180^{\circ}$ angle). Approximating the average radius to be $\left(r_{1}+r_{2}\right) / 2$, we can determine the work calculation for one average orbit. Doing so yields:

$$
\begin{aligned}
& 2 \times 10^{5}=\mathrm{F}_{\mathrm{avg}}\left(2 \pi \mathrm{r}_{\mathrm{avg}}\right) \cos 180^{\circ} \\
&=-\mathrm{F}_{\mathrm{avg}}\left[2 \pi\left(\mathrm{r}_{2}+\mathrm{r}_{1}\right) / 2\right] \\
&=-\mathrm{F}_{\mathrm{avg}}\left[2 \pi\left(7.35 \times 10^{6}+7.6 \times 10^{6}\right) / 2\right] \\
&=-\left(4.7 \times 10^{7}\right) \mathrm{F}_{\mathrm{avg}} \\
& \Rightarrow \quad \mathrm{~F}_{\mathrm{avg}}=-.0043 \text { newtons }
\end{aligned}
$$

g.) The modified conservation of angular momentum expression is:

$$
\sum \mathrm{L}_{1}+\sum \Gamma_{\mathrm{ext}} \Delta \mathrm{t}=\sum \mathrm{L}_{2},
$$

where the $L$ terms are angular momentum quantities and the $\Gamma \Delta t$ is a torque driven, impulse-related quantity (remember, the modified conservation of linear momentum equation was $\Sigma p_{1}+\sum F_{\text {ext }} \Delta t=\sum p_{2}$, where the $F_{\text {ext }} \Delta t$ term was the impulse being delivered by external forces over the time interval $\Delta t$ ).

The average external torque about the planet's orbital axis is:

$$
\Gamma_{\mathrm{ext}}=\mathbf{r}_{\mathrm{s}, \mathrm{avg}} \mathrm{x} \mathbf{F}_{\mathrm{avg}} .
$$

Noting that the frictional force $\boldsymbol{F}_{\text {avg }}$ is perpendicular to the radius vector $\boldsymbol{r}_{s, \text { avg }}$, the magnitude of the torque will simply be the product of the radius and force vectors $\left(\sin 90^{\circ}=1\right)$. Assuming the direction of the satellite's angular velocity is positive and noting that the torque slows the motion, our frictioninduced torque will be negative. As such, we can write:

$$
\Gamma_{\mathrm{ext}}=-\mathrm{r}_{\mathrm{s}, \mathrm{avg}} \mathrm{~F}_{\mathrm{avg}} .
$$

The angular momentum of the satellite will equal:

$$
\mathrm{L}=\mathbf{r}_{\mathrm{s}, \mathrm{avg}} \mathrm{x} \mathbf{p},
$$

where again the angle between the vectors is $90^{\circ}$ and the sine of the angle is 1 . As the magnitude of the momentum is $m_{s} v_{s}$, we can write in general:

$$
\mathrm{L}=\mathrm{r}_{\mathrm{s}, \mathrm{avg}} \mathrm{~m}_{\mathrm{s}} \mathrm{v}_{\mathrm{s}}
$$

Using all this information in our modified conservation of angular momentum equation, we can solve for $\Delta t$ :

$$
\begin{aligned}
& \sum \mathrm{L}_{1}+\quad \sum \Gamma_{\text {ext }} \quad \Delta \mathrm{t}=\quad \sum \mathrm{L}_{2} \\
& m_{\mathrm{s}} \quad \mathrm{v}_{\mathrm{s}, 1}-\mathrm{r}_{\mathrm{s}, \operatorname{avg}} \quad \mathrm{~F}_{\mathrm{avg}} \Delta \mathrm{t}=\quad \mathrm{r}_{\mathrm{s}, 2} \quad \mathrm{~m}_{\mathrm{s}} \quad \mathrm{v}_{\mathrm{s}, 2} \\
& \left(7.6 \times 10^{6} \mathrm{~m}\right)(400 \mathrm{~kg})(7244 \mathrm{~m} / \mathrm{s})-\left(7.475 \times 10^{6} \mathrm{~m}\right)(.004 \mathrm{nt}) \Delta \mathrm{t}=\left(7.35 \times 10^{6} \mathrm{~m}\right)(400 \mathrm{~kg})(7366 \mathrm{~m} / \mathrm{s}) \\
& \Rightarrow \quad \Delta \mathrm{t}=1.223 \times 10^{7} \text { seconds. }
\end{aligned}
$$

This rounded-off value is approximately 141 days, 13.5 hours.

## 10.6)

a.) The conserved quantities for planetary motion are angular momentum (there are no external torques acting on the planet), and energy (there is practically no frictional effect in space, and there are generally no appreciable non-conservative forces acting on planets--asteroid collisions excepted).

## b.) At $r_{\text {min }}$,

the star has $U_{1}=$ $-5 \times 10^{33}$ joules (see graph) and kinetic energy $K E_{1}=2.5 \times 10^{33}$ joules. That means the total energy of the system is $K E_{1}+$ $U_{1}=-2.5 \times 10^{33}$ joules. In addition, the sum of the potential and kinetic energies must always equal that number (energy is conserved).
Because we know the total energy in

the system, and because we have a graph of the potential energy as a function of position, we can determine the kinetic energy as a function of position for any point in the orbit. Doing that for key points (example: at $r_{\max }$, the graph tells us that the potential energy is approximately $U_{\max }=$ $-4.2 \times 10^{33}$ joules $\ldots$ that means $K E_{\max }-4.2 \times 10^{33}$ joules $=$ total energy $=$ $-2.5 \times 10^{33}$ joules, or $K E_{\max }=1.7 \times 10^{33}$ joules at that point), and remembering that the kinetic energy function mirrors the potential energy function when the total energy is constant, we can draw the kinetic energy graph as shown below.
